Azithromycin in one week quadruple therapy for \textit{H pylori} eradication in Iran

Shahrokh Mousavi, Jafar Toussy, Siamak Yaghmaie, Mehrdad Zahmatkesh

Abstract

\textbf{AIM:} To investigate eradication rates, patient compliance and tolerability of a 1-wk Azithromycin-based quadruple therapy versus the 2-wk conventional therapy.

\textbf{METHODS:} A total of 129 \textit{H pylori}-positive patients were randomized to either omeprazole 20 mg, bismuth subcitrate 240 mg, azithromycin 250 mg, and metronidazole 500 mg, all twice daily for 1-wk (B-OAzM) or omeprazole 20 mg, bismuth subcitrate 240 mg, amoxicillin 1g, and metronidazole 500 mg all twice daily for 2-wk (B-OAM). \textit{H pylori} infection was defined at entry by histology and rapid urease test and cure of infection was determined by negative urea breath test.

\textbf{RESULTS:} \textit{H pylori} eradication rates produced by B-OAzM and B-OAM were 74.1\% and 70.4\% respectively based on an intention to treat analysis, and 78.1\% versus 75.7\% respectively based on a per-protocol analysis. The incidence of poor compliance was lower, although not significantly so, in patients randomized to B-OAzM than for B-OAM (3.5\% versus 4.3\%) but intolerance was similar in the two groups (35\% versus 33.3\%).

\textbf{CONCLUSION:} 1-wk azithromycin based quadruple regimen achieves an \textit{H pylori} eradication rate comparable to that of standard 2-wk quadruple therapy, and is associated with comparable patient compliance and complications.

INTRODUCTION

\textit{H pylori} is a common human pathogen that has been shown to be a major factor in peptic ulcer disease. It has also been linked to gastric adenocarcinoma and gastric lymphoma \cite{1}.

A number of antimicrobial agents have been used in various regimens to eradicate \textit{H pylori}. Clinical trials are regularly undertaken to search for simpler but equally effective regimens\cite{2-4}. Azithromycin, a new generation macrolide, has some special attributes that suggest it would be a promising compound to be used in regimens for \textit{H pylori} eradication. It is acid-stable, has a long half-life and achieves remarkably high concentration in the gastric tissue\cite{5,6}. There have been several clinical trials of azithromycin for the therapy of \textit{H pylori} infection\cite{3,4,6,7}. As the pharmacological properties of azithromycin make it possible to use shorter courses, the problem has been to define an optimal dose and duration of azithromycin treatment in the course of therapy\cite{3,4}. On the other hand, in developed countries, regimens of one week’s duration are recommended for \textit{H pylori} eradication\cite{1,2,8} but in developing countries 1-wk regimens failed to eradicate the microbe. A minimum of 10 to 14 d of treatment were needed for eradication of the microbe, even in the presence of a favorable sensitivity profile\cite{9,10}. The aim of this study was to assess the efficacy of azithromycin in a 1-wk regimen compared with a conventional 2-wk regimen in Iran, so we compared two quadruple regimens; bismuth subcitrate, omeprazole, azithromycin, and metronidazole, for 1-wk (B-OAzM) and bismuth subcitrate, omeprazole, amoxicillin and metronidazole, for 2-wk (B-OAM) in \textit{H pylori} eradication. The safety and tolerability of the two drugs combinations were also evaluated and compared.

MATERIALS AND METHODS

Patients considered for the study included individuals 18-80 years old with upper GI symptoms that were referred to our gastroenterology clinic for upper endoscopy. Patients with \textit{H pylori} infection were included in the study. Other inclusion criteria included indication for treatment as per the National Institutes of Health (NIH)
RESULTS

The two groups were comparable in terms of common clinical variables that are summarized in Table 1. Three patients were lost to follow up (two from the B-OAM regimen and one subject from the B-OAzM regimen); also five patients discontinued the drugs because of severe side effects (three from the B-OAM regimen and two subject from the B-OAzM regimen). The remaining 121 patients completed the study as planned.

PP analysis: *H pylori* infection was eradicated in 43 of 55 patients in the B-OAzM group (78.18%, CI0.95: 64.98%-88.18%) and in 50 of 66 patients in the B-OAM group (75.75%, CI0.95: 63.63%-85.46%); the difference was not statistically significant (χ² = 0.1, P = 0.75).

In patients with peptic ulcer, *H pylori* infection was eradicated in 19 of 25 patients in the B-OAzM group (76%, CI0.95: 54.87%-90.64%) and in 28 of 37 in the B-OAM group (75.67%, CI0.95: 58.8%-88.22%); the difference was not statistically significant (χ² < 0.001, P = 0.97).

ITT analysis: *H pylori* infection was eradicated in 74.13% (CI0.95: 60.95%-84.74%) in the B-OAzM group and 70.42% (CI0.95: 58.4%-80.67%) in the B-OAM group; the difference was not statistically significant (χ² = 0.3, P = 0.58).

Complications: The overall results for side effects are summarized in Table 2. Complications were noted in 14 patients in the B-OAzM group (23.45%) and 17 patients in the B-OAM group (25.75%) with no statistically significant differences between the groups (χ² < 0.001, P = 0.96). The symptoms were mild and did not necessitate any additional treatment except in the five patients that discontinued the drugs for severe complications.

DISCUSSION

Although various regimens have been recommended for *H pylori* eradication, all of them include at least 2 antibiotics and one acid inhibitory drug[1]. In western countries,
the most effective and usual regimens for preliminary treatment include; triple regimens for at least 1 wk, and use of clarithromycin as the antibiotic of choice against *H pylori*. Metronidazole, on the other hand, has largely been eliminated from first-line *H pylori* therapy because of its intolerability and high drug resistance. However, in developing countries, effective treatments for *H pylori* vary from those used in developed countries. For example in middle east countries it has been shown that one week regimens fail to eradicate the microbe and the course of treatment should be continued for at least 10-14 d to provide for eradication. Further, clarithromycin is not appropriate use because of its high price, drug resistance and unavailability and so metronidazole is a common and effective drug in *H pylori* treatment in this setting.

Although the prevalence of *H pylori* strains that are resistant to metronidazole varies from 46%-51% in Iran, it has been shown that this drug in high doses (> 1 g) and in combination with other drugs remains effective against *H pylori*. Therefore, in Iran as also done in some Asian countries metronidazole is a very common drug used in *H pylori* eradication regimens. In Iran, the most common regimens for first-line treatment are 2-wk quadruple regimens that include: metronidazole, omeprazole, bismuth and tetracycline or amoxicillin. This conventional regimen introduced initially by Hosking, Deboer, Borody, and Laine as an effective regimen in *H pylori* treatment has confirmed efficiency of a 63%-93% eradication rate. On the other hand, due to high rates of resistance to metronidazole, furazolidone was used instead of it, as first or particularly second line treatment.

Although 2 wk regimens have been effective in *H pylori* eradication, some patients withdraw from their treatment because of the long duration and large number of tablets. Thus, in this study we showed that a quadruple regimen, where azithromycin replaced amoxicillin, the duration of the treatment can be decreased without any change in its effectiveness.

Azithromycin is a new macrolide related to clarithromycin with an effective role in *H pylori* eradication and it was reported that azithromycin has a synergic effect with esomeprazole, even in presence of drug resistance. In various studies the effectiveness of azithromycin has been evaluated in different doses from 500 mg to 3 g (1.5 g), although in most studies this drug was used for 3 d (1.5 g) as in respiratory tract infection but at this dose it has less effect than clarithromycin. However, by increasing the total dose to 3 g, it has been shown that the effectiveness of azithromycin can be restored.

This is the first study in which azithromycin was used at a prescribed amount of 3.5 g (250 mg bid for 7d) in the treatment of *H pylori* infection. Fortunately, the patients’ tolerance was excellent. There were a few side effects based on biochemical tests, but most side effects were mild and disappeared with conservative therapy without the need to terminate the treatment.

Finally, in areas where clarithromycin cannot be used because of drug resistance or unavailability, azithromycin with a total dose of 3.5 g is an appropriate and safe drug for *H pylori* eradication regimen.

The effectiveness of furazolidone based triple or quadruple regimens has been evaluated in Iran, but because of resistance to metronidazole, it seems possible that a combination of azithromycin and furazolidone instead of azithromycin and metronidazole will achieve more favorable eradication rates, although further evaluation is needed.
